ABSTRACT

We test whether European countries or US states who experienced their first death from COVID-19 at a later date have fewer deaths from COVID 60 and 100 days after the start of the pandemic in their borders. Our sample consists of 29 European countries associated with the European Union and 50 U.S. states and we control for a number of demographic, economic and health-policy related factors that are likely to influence mortality. We find that late starting countries or states registered fewer deaths from COVID-19. Countries/states' differential reliance on partial or complete lockdown policies helps explain an area's advantage of being a late starter.

Keywords: SARS-CoV-2, mortality, Western countries, medical technology, lockdowns.

Landoni et al. (2020) compared death rates at 50 days after COVID-19's onset in 14 Western countries and found that the later a country first experienced at least 0.1 death per million inhabitants, the lower the death rate 50 days after onset. We add to their study as follows: we examine the association between cumulative deaths at 60 and 100 days after onset of COVID-19 in a particular area based on a larger sample: 29 European countries and 50 U.S. states,¹ and use regression analysis to control for a number of factors likely to influence mortality.

We define onset in a particular area as the day that area experienced its first death from COVID-19 (it ranged from February 15 (France) to April 13 (Wyoming)).² 'Days since onset in FR' is defined as the number of days that elapsed from the time of the first death in France until the first death in the area. Multivariate regression models of the logarithm of cumulative deaths give us the percentage growth/decline in deaths resulting from a unit change in a variable. The models in columns 1 to 2, Table 1, control for population size, proportion of young adults living with their parents, percent of the population over 65, percent urban, Gross Domestic or State Product per capita, rent levels, tests per capita, number of hospital beds, a control for whether the area is in the US versus the EU, whether a government is left-leaning, and an interaction between left-leaning and US. Accordingly, cumulative deaths 60 days past onset declined by 7.4 percent for every extra day a country was saved from the pandemic (col.1) and by 10 percent when cumulative deaths are measured 100 days past onset (col. 2). Since we control for population size our results can be interpreted as associations between timing of onset and cumulative deaths per capita. These results support Landoni et al's (2020) finding and apply to US states and European countries.

Landoni et al (2020) mention that later starters may have learned from other countries' experience with preventative strategies such as lockdowns. To test for that possibility, we run regressions that also include whether the country or state had a full or partial lockdowns and number of days from onset to implementation of lockdowns. Results, reported in Columns 3 and 4, indicate smaller coefficients of days from onset. For example, an extra day since onset reduces cumulative fatalities at 100 days of epidemic only by 7.9% (column 4), not by 10% (column 2). Learning about the effectiveness of lockdowns could thus have helped later starters. Alternative explanations include improved pathophysiologic understanding, better testing technology, and more widespread adoption of personal protections. It is hoped that future work will examine this question with more detailed data of the type used by Laliotis and Minos (2020) or Amuedo-Dorantes et al (2020).

¹ 26 EU members, UK, Switzerland and Serbia.
